Abstract

Background - The clavicle is a complex bone structure, which has been globally studied in purpose of generating a suitable, correct and economical treatment of clavicle fractures. For measurement of clavicle there are several methods includes hand measurements, 2D and 3D measurements. The most expressive variations are the length and width. Variations in bending in the axial plane are present, especially at the acromial end. Curvature variation is present in lesser degree. Anatomical variations in the clavicle of relevance to form intramedullary fixation.

Objectives - The purpose of this study was to measure length, medial angle and lateral angles. To know about comparative differences between curvatures of the right and left clavicles.

Methods – 320(185 male and 135 females) clavicles used for this study collected from the first year M.B.B.S student from different medical colleges in south India during the period 2007 – 2012. These angles were measured with the help of a protractor.

Results – The average mean length of male was 142.90±10.59mm, the average mean length of female was 132.30±10.44mm. The average mean length of right male clavicle was 142.10±11.70mm and left was 143.8±9.55mm. The average mean length of right female clavicle was 131.12±12.22mm and left was 131.10±9.02mm. The range of medial angle of right clavicle was 136° to 163° and left was 135° to 166°. The range of lateral angle of right clavicle was 122° to 162° and left was 126° to 168°.

Conclusion - The measurements of clavicles helps for orthopaedic surgeons, anatomists and anthropologists.

Key words – Clavicle, Medical Angle, Lateral angle, Clavicle length.

INTRODUCTION

The human clavicle is described as a long bone. It has a shaft and two ends that are sternal and acromial ends. The shaft is gently curved with convexity forwards in its medial two-thirds and concavity forwards in its lateral third. The clavicle is thicker and more curved in manual workers and its ridges for muscular attachment are better marked[1,2]. Clavicle fractures are common and occur most frequently (80-85%) in the middle third. Although usually treated conservatively, there is increasing recognition of the morbidity associated with displaced fractures, and also of the increased rate of non-union of fractures in this zone. The improved benefits derived from fixation have resulted in renewed interest in fixation of clavicle fractures. While plating and nailing have been popularised, an external fixation device can also be effectively employed for the midthird fractures as reported by Schuind, Demiralp, Tomic and others[3,4,5]. Recent studies have shown the efficacy of open reduction and internal plate fixation with high union rate and low complication rate. Several complications like lack of fixations, breaking or loosening of the plate happen [6,7,8] and are partially due to bending of a straight plate. We believe that a set of osteosynthesis plates that is adapted to the shape variation of the human clavicles will not only reduce these complications but will also minimize the amount of bending required to adapt a plate to a specific clavicle during surgery.

In Primates, the shoulder complex includes 3 bones that are scapula, clavicle, and humerus, more than 20 muscles, the exact number depending on the particular species and 4 joints working together. The clavicle has been considerably less studied from a comparative perspective than has the humerus and scapula. Clavicle morphology is important element to determining upper limb locomotion behaviour. The design of fixation devices depends to a large extent on the anatomical and physical characteristics of this bone. In order to get data on the normal variation of the dimensions of the clavicle to assist with design, the previous studies reported that the physical characteristics and appearance of the clavicle to assist with gender identification and length[9,10]. The clavicle having two curvature that are lateral and medial curvatures. Lateral curvature is shorter and medial curvature is longer and shows a slight
difference between genders. The main differences are the length and diameter. In the sagittal plane, the lateral end has an elliptic shape, which becomes circle shaped in the medial end. The inflection point lies around the thinnest point of the bone. The main difference in curvature lies at the lateral side. Attention to the length and curvature is needed when using a plate and to the width and diameter when using an intramedullary nail. The purpose of this study was to measure length, medial angle and lateral angles. To know about comparative differences between curvatures of the right and left clavicles.

**MATERIALS AND METHODS**

320 (185 male and 135 females) clavicles used for this study collected from the first year M.B.B.S student from different medical colleges in south India during the period 2007 – 2012. These angles were measured with the help of a protractor.

**RESULTS**

The average mean length of male was 142.90±10.59mm, the average mean length of female was 132.30±10.44mm. The average mean length of right male clavicle was 142.10±11.70mm and left was 143.8±9.55mm. The average mean length of right female clavicle was 131.12±12.22mm and left was 131.10±9.02mm. The range of medial angle of right clavicle was 136° to 163° and left was 135° to 166°. The range of lateral angle of right clavicle was 122° to 162° and left was 126° to 168°.

**DISCUSSION**

The clavicle is considered a long bone as it has a medullary cavity and an epiphysis at either end to permit growth. The clavicle is the first fetal bone to undergo primary ossification, and its medial epiphysis is the last to fuse. However, whereas other long bones undergo initial endochondral ossification, the clavicle ossifies via intramembranous ossification with no prior endochondral ossification. The two primary ossification centers appear by the 6th week intrauterine and fuse together about one week later. After the osteoid matrix is laid down, cartilage appears at the acromial and sternal ends of the bone, at which point growth becomes a combination of endochondral and membranous ossification. The medial cartilaginous mass contributes more to clavicular growth in length than does the lateral mass, perhaps as much as 80% of the bone length. The combination of the spatial location of the two ossification centers at either end of the bone and endochondral ossification at these sites gives the clavicle its unique s-shape by 8-9 prenatal weeks. The bone attains its adult form by 11 prenatal weeks. Growth slows after birth until the growth spurt between 5 and 7 years, then slows again until the pubertal growth spurt. During adolescence secondary ossification centers appear at the medial and lateral ends of the clavicle. Medial epiphysial ossification begins at the onset of puberty, but the medial epiphysis does not fuse to the shaft completely until some 10 years after its initial appearance. Consequently, medial epiphysial fusion has proven useful in estimating skeletal age in young adults. The epiphysis appears initially as a small speck of bone in the center area of the sternal end and spreads until it nearly covers the entire medial surface. The timeline for clavicular maturation: a well-defined medial flake appears between 16 and 21 years; the flake covers the majority of the medial surface between 24 and 29 years; complete fusion occurs between 22 and 30 years[11].

According to Toon Huysmans et al, the most expressive variations are the length and width. Variations in bending in the axial plane are present, especially at the acromial end. Curvature variation is present in lesser degree. The average length is 163±11 mm for the general population, 169±10 mm for the male and 154±8 mm for the female population. The left clavicle is on average 1.6 mm larger than the right one. The biggest diameter is at the extremities, which decrease towards the middle. The difference between the genders is 1.5-2 mm. The smallest average diameter is 12±1 mm and is aligned with the inflection point. The axial diameter is up to 50% bigger laterally and 10% smaller medially. The lateral curvature is shorter and, in males, is more accentuated. The medial curvature is longer and shows a slight difference between genders. The main differences are the length and diameter. In the sagittal plane, the lateral end has an elliptic shape, which becomes circle shaped in the medial end. The inflection point lies around the thinnest point of the bone. The main difference in curvature lies at the lateral side. Attention to the length and curvature is needed when using a plate and to the width and diameter when using an intramedullary nail[12].

The same study divided the clavicle as five zones as follows. Zone I is represent the medial and lateral ends of the clavicle. Zone II point which represents the lateral most extent of the insertion of the sternocleidomastoid muscle superiorly, and sternoclavicular ligament inferiorly. Zone III is point at the junction of the medial and lateral thirds of the clavicle. Zone IV is the junction of the middle and lateral thirds of the clavicle. Zone V is the midpoint of the outer third where a significant change of cross-sectional profile occurs between zones IV and V. The author believed that the zone categorisation to be relevant in order to define the ideal area for the attachment and design of a fixation device. According to author the knowledge of the appropriate area for fixation and the length of bone available for application of a fixation device are vital to optimal design of an external fixation device. In same study found that the average length available for application of a device is 40 to 60 mm, but laterally this may be limited to 40 to 55 mm as defined by zones I and II and zones IV and V respectively. The cross-sectional profile will also influence the ease or difficulty with which an external fixation device can be securely applied. From the cross-sectional profile it can be seen that zones I and II, the medial end, can be consolidated into one group with the profile being overwhelmingly tubular or somewhat quadrilaterally facet, lending it to a variety of fixation...
options and inclinations. At the other end, the lateral end is flattened supero-inferiorly and fixation is more intuitively restricted to perpendicular to the superior/inferior surfaces. In its mid portion the clavicle undergoes a transition from a faceted surface to a more rounded or ovoid profile which favours anterior and superior placement of a fixation device[13].

In present study the average mean length of male was 142.90±10.44mm, the average mean length of female was 132.30±10.44mm, our results are near to studies of following. The overall length of the clavicle measured in this study of J Walters was 150.1 mm by direct dry bone measurement. Ahmad et al who recorded a mean length of 136.2 mm and range was 112.6–172.0 mm in a radiographic study[14], Gumina et al who recorded a mean of 138 ± 12.3mm[15] and Galley et al was 138.4mm and range was113.8–167.6mm in wet cadaver dissections[16]. According to study of Parsons FG, the medial angle of English clavicle was 154° on the right side and 154° on left side.in same study found that the lateral angle of clavicle was 149° on right and 149.5° on left side, same study also calculated the sum of both angles of the clavicle was 302.5° on right and 303.5° on left side[17]. In study of Terry RJ found that the mean medial and lateral angles of clavicle of American Negroes were 152.32° and 141.24° on the right and 152.60° and 144.68° on the left side respectively. The same study also calculated the average sum of both angles was 292.94° on the right and 296.42° on the left side[18]. The study Kaur H et al recorded that the average medial angle of clavicle was 151.68° on the right and 151.89° on the left side, the side differences in the mean medial angle on the two sides were statistically insignificant. Same study recorded that the average lateral angle of the clavicle of the north-west India was 143.96° on right and 148.46° on the left side. They also recorded that the sum of the angle of the clavicle of the north-west Indian was 292.55° on right and 297.18° on the left side[19]. The morphometric values of clavicle helps for orthopaedic surgeons, anthropologists, forensic and anatomy practice.
